Review Article

Propionibacterium acnes infection after shoulder surgery

Benjamin K. Kadler, Saurabh S. Mehta, Lennard Funk

ABSTRACT

Propionibacterium acnes has been implicated as a cause of infection following shoulder surgery, may occur up to 2 years after the index operation and has been shown to be responsible for up to 56% of shoulder infections after orthopedic implant. Male patients within the population undergoing shoulder surgery are particularly at risk, especially if their shoulder surgery involved prosthesis or was posttraumatic. P. acnes infection can be difficult to diagnose clinically and laboratory techniques require prolonged and specialized cultures. Usual inflammatory markers are not raised in infection with this low virulence organism. Delayed diagnosis with P. acnes infection can result in significant morbidity prior to prosthesis failure. Early diagnosis of P. acnes infection and appropriate treatment can improve clinical outcomes. It is important to be aware of P. acnes infection in shoulder surgery, to evaluate risk factors, to recognize the signs of P. acnes infection, and to promptly initiate treatment. The signs and symptoms of P. acnes infection are described and discussed. Data were collected from PubMed™, Web of Science, and the NICE Evidence Healthcare Databases - AMED (Ovid), BNI (Ovid), CINAHL (EBSCO), Embase (Ovid), HMIC: DH-Data and Kings Fund (Ovid), Medline (Ovid), and PsycINFO (Ovid). The search terms used were “P. acnes,” “infection,” “shoulder,” and “surgery.” In this review, we summarize the current understanding of the prevention and management of P. acnes infection following shoulder surgery.

Key words: Infection, orthopedic, Propionibacterium acnes, prostheses, shoulder

INTRODUCTION

Propionibacterium acnes is a nonspore-forming, anaerobic, Gram-positive bacillus. Paul Gerson Unna first described it in 1896 as acne bacillus and in 1933, it was assigned to the genus of Propionibacterium. It is of low virulence and is often a commensal in the lipid-rich sebaceous follicles and deep layers of the skin, conjunctiva, external auditory canal, respiratory tract, and intestinal tract. P. acnes mostly colonizes the pilosebaceous follicles in the skin of the upper body, including the head, neck, shoulders, and especially the axilla. Its pathogenic activity has been shown in endocarditis, endophthalmitis, septic arthritis, osteomyelitis, chronic prostatitis, sarcoidosis and synovitis, acne, pustulosis, hyperostosis, and Osteitis syndrome. There are hemolytic and nonhemolytic phyotypes, with the former representing the most pathogenic strain. P. acnes adheres to cells, biofilms, and surfaces by means of antigenic proteins which can initiate an inflammatory response within the joint. They also secrete cytotoxic chemicals and enzymes designed to degrade body tissues and the shoulder capsule. Furthermore, P. acnes are able to secrete and live within an extracellular polysaccharide biofilm, aiding micro-colony formation, as well as avoiding phagocytosis, and surviving macrophage engulfment. The combination of the bacterium-enterocyte limb distribution and its role in prosthetic joint infection (PJI), accounting for up to 56% of shoulder infections involving orthopedic implants, is now coercing...
shoulder surgeons to consider *P. acnes* as an “orthopedic pathogen.” We present a comprehensive review of the current information on the identification and management of *P. acnes* following shoulder surgery.

**MATERIALS AND METHODS**

This review focuses on recent studies of: The patient subgroups that are more at the risk of infection; the pathophysiology of *P. acnes* in shoulder infections; the effect of *P. acnes* on the postoperative healing process of the shoulder; and the prevention and management of shoulder infection with *P. acnes*. Information was also gathered about the incidence of *P. acnes* infection. A schematic showing the search and selection strategy is shown in Figure 1. Searches were performed with PubMed®, Web of Science, and the NICE Evidence Healthcare Databases — AMED (Ovid), BNI (Ovid), CINAHL (EBSCO), Embase (Ovid), HMIC: DH-Data and Kings Fund (Ovid), Medline (Ovid), and PsyclINFO (Ovid). The search terms used were “*P. acnes*,” “infection,” “shoulder,” and “surgery.”

**Incidence**

**Arthroplasty**

Over the past decade, *P. acnes* has become increasingly recognized as a cause of infection in orthopedic surgery, especially postarthroplasty. In shoulder arthroplasty, infection rates for anatomical arthroplasty have been reported to be <4%, but as high as 18% following reverse polarity arthroplasty. In one study, the most common bacteria identified were *Staphylococcus epidermidis* and *P. acnes*. In a retrospective review (over 7 years) from Canada, 80 patients were identified who had positive joint cultures after primary shoulder arthroplasty and *P. acnes* was found to be the second most common pathogen in 25% of participants. A study of PJI after total shoulder arthroplasty (in the last 33 years) found that *Staphylococcus* was the dominant organism, whereas from 2001 to 2008, the incidence of *P. acnes* was found to be almost as high as *Staphylococcus*. This increasing incidence could be the result of changes in the microbiology of shoulder infections, heightened awareness of the organism, better surveillance, or improved laboratory diagnostic techniques.

**Soft tissue**

Concerning soft tissue shoulder surgery, deep infection after rotator cuff repair can occur in up to 1.9% of cases, with studies finding *P. acnes* to be the most common causative organism. Evidently, *P. acnes* appears to be a prominent organism in postoperative shoulder infections and is becoming increasingly prevalent.

**Risk factors**

Recorded risk factors for infection in shoulder arthroplasty, including *P. acnes* infection, are male gender, surgery of the upper body (especially the shoulder), increased duration of surgery, and interestingly, being the first surgery of the day. The predominance of *P. acnes* in shoulder infections has been linked with the presence of the axillary lymph nodes. Culturing of the epidermis during revision surgery found that 16/18 males had *P. acnes* infection, whereas only 7/12 female subjects tested positive. Further studies have revealed that male gender and prior prosthetic implants are significant risk factors for *P. acnes* infection of the shoulder. The male predisposition, of over 2.5 times higher risk than females after shoulder arthroplasty, has been linked with the habitat of *P. acnes* being within the hair follicles and, therefore, the upper body of males would harbor more of the bacterium. Moreover, males lacking signs of infection have a higher risk of *P. acnes* positive cultures during arthroplasty. Interestingly, posttraumatic shoulder arthroplasty has 3 times higher risk of infection than elective surgery. Reverse total arthroplasty also carries increased risk. Younger age was identified as a risk factor, with each year of increasing age causing a risk reduction of 5%, however, body mass index and diabetes mellitus, which are usually associated with increased risk, were not found to be risk factors. From the literature, it is evident that patients most at the risk of *P. acnes* infection are young people, males, those who have undergone upper limb surgery (especially reverse shoulder replacements), and posttraumatic surgery.

**Diagnostic difficulties**

Despite technological advances, the diagnosis of shoulder infections due to the low virulent *P. acnes* remains challenging. The nonspecific clinical presentation, inadequate culture performance, and the inability to accurately interpret positive cultures can delay diagnosis. Inflammatory markers, usually indicative of infection, may not be raised with *P. acnes* infection. In one study, C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) were both raised in only 10% of patients with *P. acnes* infections of the shoulder. Furthermore, the sensitivities of CRP and ESR in shoulder
infections were found to be 42% and 16%, respectively, whereas in the lower limbs, the sensitivities for CRP and ESR were found to be 88% and 75%, respectively. Unlike in the lower limb, these inflammatory markers have been shown to be poor indicators of postoperative shoulder infections. These data fit well with the distribution of P. acnes and its indolent nature. Owing to slow growth, P. acnes need longer culture times of up to 2 weeks, making infection harder to identify. Furthermore, lowering the threshold for diagnosis (concentration of neutrophils in the tissues) would increase sensitivity because of the relatively low inflammatory response to the presence of P. acnes, Interleukin-6 (IL-6), a factor involved in inflammation, has been studied as a way of detecting indolent infections of the shoulder and may represent as a possible new predictor. Analysis of aspirated synovial fluid from 32 patients undergoing revision surgery for suspected PJI after arthroplasty for IL-6 titers showed that IL-6 levels were considerably increased in patients infected with P. acnes. In a study presented at the British Elbow and Shoulder Society, P. acnes was found in 38% of patients (n = 101 patients) undergoing arthroscopic shoulder surgery for rotator cuff with enrichment medium. Furthermore, authors have concluded that to improve reliability, deoxyribonucleic acid and polymerase chain reaction tests are being developed, as contamination cannot be reliably ruled out via enrichment medium.

**Clinical presentation**

A common assumption is that P. acnes infection originates in the epidermis of the patient at reliably ruled out via enrichment surface to the surgical site. Surface sterilization before surgery does not, however, eradicate the bacterium as the organism actually resides deep in the sebaceous glands. Scalpel incisions slice through these follicles seeding the bacteria. Innovative methods of sterilization may, therefore be required to penetrate the dermis and reduce P. acnes spread. The need for intraoperative screening of wounds and prolonged cultures to assess the risk of developing a postoperative shoulder infection has been emphasized. For low-grade P. acnes shoulder infections, pain may be the only symptom, followed by stiffness, with all other signs of infection, including fever, usually being absent. Prolonged low-grade infection can result in loss of normal function of the joint or progress to sepsis. The common patterns of clinical presentation are displayed in Table 1.

**Table 1: Presentation of postoperative Propionibacterium acnes infection in the shoulder**

The mean time from index surgery to diagnosis of P. acnes infection was 1.8 years following rotator cuff repair surgery, whereas after arthroplasty, it has been shown to be 2.1 years. It was also suggested that the variance in the clinical presentation of shoulder infections can not only be due to the nonspecific clinical manifestation of P. acnes, but also due to co-infection with other species of bacteria within the surgical site.

**Prosthesis failure**

Infection is the most common cause of joint replacement failure in the shoulder, but some of the diagnosed aseptic loosening may also be due to low-grade P. acnes infection. Of the 63 cases of aseptic loosening and 63 cases of PJI, in one cohort study assessing knee, hip, shoulder, and elbow revision surgeries, P. acnes was found in 12 and 2 cases, respectively, but none in cases of mechanical failure. P. acnes could be a causative factor in some cases which were thought to be as aseptic loosening of joint implants and requires further research. In a study including 75 patients undergoing shoulder revision arthroplasties with positive intraoperative cultures, P. acnes was found in 60%
of cases.\(^{[3]}\) 10 out of these 75 patients required re-revision, 7 had positive bacterial cultures of which 5 were \textit{Propionibacterium acnes} (71%).\(^{[3]}\)

**Drug resistance**

Patient knowledge about \textit{Propionibacterium acnes} is mostly limited to acne vulgaris, a skin infection present in the vast majority of young adults and teenagers.\(^{[3,4]}\) Hormonal changes and genetics cause sebaceous gland inflammation, dysfunction, and proliferation, providing an environment for the opportunistic \textit{Propionibacterium acnes}.\(^{[3]}\) The treatment of this skin condition with experimental courses of broad-spectrum antibiotics, often combined with poor compliance, is thought to be a contributor to antibiotic resistance.\(^{[8]}\) Gold standard antibiotics such as penicillins, vancomycin, tetracyclines, rifampicin, and erythromycin often eradicate the bacterium, however, over half of \textit{Propionibacterium acnes} cultures now carry resistance to more than one of the above antibiotics.\(^{[8,9,10,11]}\)

**Treatment and outcomes**

With the increase in shoulder operations\(^{[23]}\) and prevalence of \textit{Propionibacterium acnes},\(^{[23]}\) advances in the management of such infections have been accelerated.\(^{[23]}\) Superficial surface infections can be controlled using wound care and antibiotics, however, deeper surgical site infection requires irrigation and surgical debridement with antibiotic treatment. Surgical debridement alone cannot eliminate infection, and intravenous antibiotic therapy may last up to 6 weeks.\(^{[5,6]}\) Excess scar tissue, due to repeated surgery, can deteriorate functional outcome.\(^{[13]}\) A retrospective study evaluating the characteristics and clinical outcomes of PJI’s of the shoulder indicated that clinical trials have provided little evidence of the best antibiotic regimes for \textit{Propionibacterium acnes}.\(^{[5]}\) Vancomycin and clindamycin are first-line for deep \textit{Propionibacterium acnes} infections of the shoulder; however, first-generation cephalosporins and penicillins may have a greater role in the future.\(^{[5]}\) Rifampin and daptomycin combined (to avoid rifampin resistance) have been shown to yield the highest cure rate of 63% in an animal cage model.\(^{[34]}\) In established low-grade infections with \textit{Propionibacterium acnes}, exchange of the prosthesis might provide the best clinical outcome.\(^{[13]}\)

**Prevention**

The increasing prevalence of \textit{Propionibacterium acnes} and other bacteria likely to infect during a prosthetic shoulder operation has provided a demand for innovative methods of reducing contamination. The application of a liquid cyanoacrylate-based sealant onto the skin of patients before surgery to act as a barrier for surface infection, combined with the iodine wash, has been found to reduce rates of infection compared to just the iodine wash alone.\(^{[35]}\) In a prospective study of 150 patients, there was no difference in Chloraprep (2% chlorhexidine gluconate and 70% isopropyl alcohol), DuraPrep (0.7% iodophor and 74% isopropyl alcohol), or povidone-iodine scrub, and paint (0.75% iodine scrub and 1.0% iodine paint) to eliminate \textit{Propionibacterium acnes}, although Chloraprep was most effective in eliminating coagulase negative \textit{Staphylococcus} when used for preoperative preparation.\(^{[35]}\) These two were the most common native organisms in shoulder cultures.\(^{[35]}\)

**Propionibacterium acnes and arthritis**

\textit{Propionibacterium acnes} might play a role in the development of arthritis of the shoulder.\(^{[5]}\) It has previously been shown that the injection of \textit{Propionibacterium acnes} into the joints of rats leads to arthritis.\(^{[15]}\) Furthermore, there is a hypothesis that the relapsing-remitting cycles of pain in osteoarthritis may be linked to the flare-ups of the bacterial population within the joint.\(^{[5]}\) This research was initiated due to the findings of high incidence of \textit{Propionibacterium acnes} in shoulders before arthroplasties, suggesting a correlation with arthropahty.\(^{[3]}\) A recent publication, however, contradicts these findings.\(^{[14]}\) Upon microbiological and histopathological analysis of tissue samples from 32 patients diagnosed with shoulder arthritis undergoing primary shoulder arthroplasty, no patients had findings or cultures compatible with \textit{Propionibacterium acnes} infection.\(^{[3]}\) This study emphasizes the need for strictly controlled specimen collection during surgery to reduce contamination and the need to review prophylactic antibiotic regimens.\(^{[14]}\)

**Current policy at senior author’s institution**

Shoulder PJI is uncommon, but represents a significant problem. We follow common precautions for shoulder joint arthroplasty as in the knee and hip. We have preoperative screening for infection, double preparation of the joint in an anesthetic room and operating theater, and use Chloraprep. To reduce the risk of infection, we ensure the isolation of the axilla, avoid incisions near the axilla, thoroughly lavage inside the joint, and give antibiotics as per microbiological guidelines locally. Antibiotic-impregnated cement can be used as well as repeat antibiotics in prolonged surgery (>2 h), if indicated, and separate postoperative wards for arthroplasty patients are utilized. For \textit{Propionibacterium acnes}, however, the most important aspect is to keep a low index of suspicion in cases of persistent postoperative pain. We have a low threshold for performing open controlled biopsy in such cases for microbiology and histopathology. We closely liaise with microbiology and pathology for PJI as we feel prolonged cultures and clinical-microbiological correlation are important to diagnose \textit{Propionibacterium acnes} infection. If biopsies are found to be positive, we perform a two-stage revision and treat with antibiotics as per sensitivities. Second stage is only performed after a clear, open biopsy.

**CONCLUSION**

\textit{Propionibacterium acnes} is a common cause of infection following shoulder surgery and is responsible for 1-in-2 shoulder infections after orthopedic implant. Younger men, among the population undergoing shoulder arthroplasty, are particularly at risk. \textit{Propionibacterium acnes} infection can be difficult to diagnose and delayed diagnosis can result in significant disease states leading up to prosthesis failure. With an increasing rate of antibiotic-resistant bacteria, \textit{Propionibacterium acnes} infection is becoming increasingly difficult to treat. In this review, we summarized the current understanding of the risk factors, clinical presentation, and management of \textit{Propionibacterium acnes} infection following shoulder surgery.
