ABSTRACT

Aim: The aim of this study is to assess, (1) the relationship between cervical vertebrae maturation and mandibular canine calcification stages; and (2) whether the mandibular canine calcification stages can be used as indicators to determine skeletal maturity. **Materials and Methods:** A descriptive, retrospective, and cross-sectional study was designed. A null hypothesis was proposed that there was no relationship between cervical vertebrae maturation and the mandibular canine calcification stages. Pre-treatment orthopantomograms (OPGs) and lateral cephalograms of 99 males and 110 females of Rwanda ethnicity were selected. The cervical vertebrae maturation index (CVMI) proposed by Hassel and Farman was used to evaluate the skeletal maturation level, and the mandibular canine calcification stages were assessed with the Demirjian Index (DI). **Results:** A significant association was found between the CVMI and DI stages, as evaluated by the Pearson contingency coefficient values (0.599 for males and 0.719 for females). Canine stage F in males and canine stage E in females could represent the CVMI 2 stage and indicate the onset of a period of accelerating growth. **Conclusions:** The mandibular canine calcification stages might be clinically used as maturity indicators of the pubertal growth period, but only during the onset and accelerating phases.

Key words: Cervical vertebrae, Demirjian index, mandibular canine, orthodontics, skeletal maturity

Introduction

Knowledge of the status of the pubertal growth spurt of an individual is important for a clinician, as it influences diagnosis, treatment planning, and the eventual outcome of the orthodontic treatment.^[1,2] The skeletal maturity can be assessed by inspection of the ossification-related changes in the hand–wrist and the cervical vertebrae regions assessed on the radiographs.^[3] The hand–wrist radiograph has been commonly used for skeletal maturity assessment.^[1] The cervical vertebrae maturation indicators on the lateral cephalograms have also been found to be reliable skeletal maturation predictors.^[3]

Studies have proposed the assessment of dental calcification stages to determine the level of skeletal maturation. It was concluded that a strong relation exists between dental maturity and skeletal maturity to evaluate the skeletal growth status.^[4,5] Relationships between the calcification stages of various mandibular teeth and skeletal maturity have been reported, with variable significance.^[1] Mandibular canine calcification has been found to be a reliable indicator in some studies,^[6-8] while others have refuted the claim.^[9-11]

The objective of this study was to investigate the relationship between the stages of cervical vertebrae maturation and permanent mandibular canine calcification. A null hypothesis was proposed that there was no significant relationship between cervical vertebrae maturation and the mandibular canine calcification stages.

Materials and Methods

It was a descriptive, retrospective, and cross-sectional research project. Good quality, pretreatment OPGs and lateral cephalograms of 209 subjects (99 males and 110 females) of Rwanda ethnicity were selected from the records of orthodontic patients.

Selection criteria: The inclusion criteria were as follows:

- Chronological age ranging from seven to nineteen years
- Normal overall growth and development
- Absence of abnormal dental conditions, such as, impaction, transposition, and congenitally missing teeth
- Absence of a previous history of trauma or disease to the face and neck
- No gross skeletal deformities, for example, clefts, hemiatrophy, hypertrophy, and so on, and no congenital deformity
- Absence of previous orthodontic treatment
- No permanent teeth extracted

All radiographic assessments were performed by a single examiner on a back-illuminated radiographic view box in a darkened room.

Evaluation of cervical vertebrae maturity (CVMI) on a lateral cephalogram: The CVMI was evaluated by using the method proposed by Hassel and Farman^[3] [Table 1].

Evaluation of dental maturity (DI) on a panoramic radiograph: The development stages of mandibular left canine were assessed according to Demirjian *et al.*^[12] (Demirjian Index, DI) [Table 2]. If the left side tooth was not clear, then the right side tooth was evaluated.

Randomly selected records of 15 patients were re-evaluated after two weeks of the first evaluation, to test the reproducibility of the assessments of DI and CVMI, and the data was evaluated in terms of the weighted kappa statistics for DI and CVMI. The kappa statistics for intraobserver agreement were 0.82 for DI assessments and 0.89 for CVMI assessments, showing acceptable intraobserver agreement during assessments.

Table 1: Cervical vertebrae maturation indicators (CVMI, Hassel and Farman, 1995)

Stage	Amount of growth expected	Characteristics
1-Initiation	80-100%	C2, C3, and C4 inferior vertebral body borders are flat. Vertebrae are wedge-shaped. Superior vertebral borders are tapered posterior to anterior
2-Acceleration	65-85%	Concavities are developing in the inferior borders of C2 and C3. The inferior border of C4 is flat. The bodies of C3 and C4 are nearly rectangular in shape
3-Transition	25-65%	Distinct concavities are seen in the inferior borders of C2 and C3. A concavity is beginning to develop in the inferior border of C4. The bodies of C3 and C4 are rectangular in shape
4-Deceleration	10-25%	Deceleration of adolescent growth spurt. Small amount of adolescent growth expected. Distinct concavities in the inferior borders of C2, C3, and C4. C3 and C4 are nearly square in shape.
5-Maturation	5-10%	Final maturation of the vertebrae takes place during this stage. Insignificant amount of adolescent growth is expected. Accentuated concavities of the inferior vertebral body borders of C2, C3, and C4. C3 and C4 are square in shape
6-Completion	Little or no growth	Adolescent growth is completed. Deep concavities are seen in the inferior borders of C2, C3, and C4. C3 and C4 heights are greater than widths

Table 2: Dental calcification stages using the demirjian index (DI)

Stage	Characteristics
A	Calcification of single occlusal points without fusion of different calcifications
B	Fusion of mineralization points; the contour of the occlusal surface is recognizable
C	Enamel formation has been completed at the occlusal surface, and dentin formation has commenced. The pulp chamber is curved, and no pulp horns are visible
D	Crown formation has been completed to the level of the cemento-enamel junction. Root formation has commenced. The pulp horns are beginning to differentiate, but the walls of the pulp chamber remain curved
E	The root length remains shorter than the crown height. The walls of the pulp chambers are straight, and the pulp horns have become more differentiated than in the previous stage. In molars, the radicular bifurcation has started to calcify
F	The walls of the pulp chamber now form an isosceles triangle, and the root length is equal to or greater than the crown height. In molars, the bifurcation has developed sufficiently to give the roots a distinct form
G	The walls of the root canal are now parallel, but the apical end is partially open. In molars, only the distal root is rated
H	The root apex is completely closed (distal root in molars). The periodontal membrane surrounding the root and apex is uniform in width throughout

Statistical Analysis

The statistical analyses were performed with SPSS 13.0, SPSS Inc, Chicago, Ill., and Epi Info 3.4.3 (CDC, Illinois). Descriptive statistics were applied for both genders to determine the percentage distribution of subjects, the means and standard deviations of the chronological ages for the stages of CVMI, and DI stages of mandibular canines. Cross-tabulation was done to find the distribution of the DI stages among the CVMI stages, stratified by the gender. Mann Whitney / Wilcoxon Two-sample test (Kruskal Wallis test for two groups), the Pearson chi-square test values, and Pearson contingency coefficient were also estimated to determine the relationship between DI and CVMI. A *p*-value of < 0.01 was considered as statistically significant.

Results

The study involved the records of 47.4% (n = 99) males and 52.6% (n = 110) females. The age range of the study sample was from seven years to eighteen years seven months. The mean age of the males was 13.27 years (SD = 2.1 years), of females was 12.89 years (SD = 2.26 years), and that of the total sample as 13.08 years (SD = 2.18 years), [Table 3].

Table 4 shows the percentage distribution and mean age at different CVMI stages. Each stage appeared earlier in females than in males, consistently [Figure 1]. Mann Whitney / Wilcoxon Two-sample test (Kruskal Wallis test for two groups) showed highly significant differences among various CVMI stages in both the genders (Females, Chi square $\chi^2(5) = 81.57$, *P* < 0.001; and Males, $\chi^2(4) = 59.08$, *P* < 0.001).

Table 5 shows the mean age at different DI stages of mandibular canines. Females achieved subsequent maturation stage of mandibular canines earlier [Figure 2]. Mann Whitney / Wilcoxon Two-sample test (Kruskal Wallis test for two groups) showed highly significant differences among various DI stages in both the genders (Females, $\chi^2(3) = 50.74$, *P* < 0.001; Males, $\chi^2(2) = 40.67$, *P* < 0.001).

Table 6 shows the association and distribution between the DI stages of mandibular canines and CVMI stages in males. The $\chi^2(8)$ was highly significant at 55.54 (*P* < 0.001). The Pearson contingency coefficient was 0.599, showing a significant association between DI and CVMI. In males,

Table 3: Showing sample distribution and mean age

	Total	Males	Females
Sample size	209	99	110
% Sample size	100 %	47.4%	52.6%
Mean age	13.08±2.18	13.27±2.1	12.89±2.26
Age range	7-18.58	8.83-18.58	7-18.42

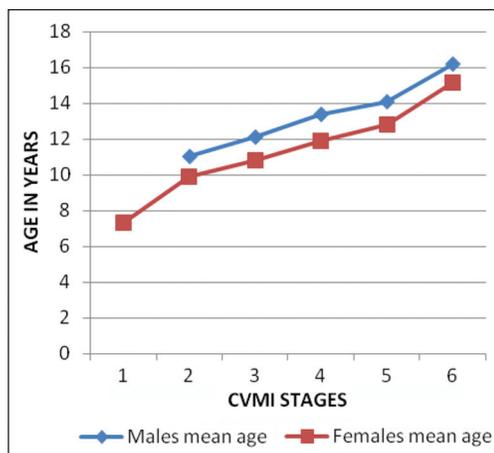

Figure 1: Mean age at each CVMI stage in both genders

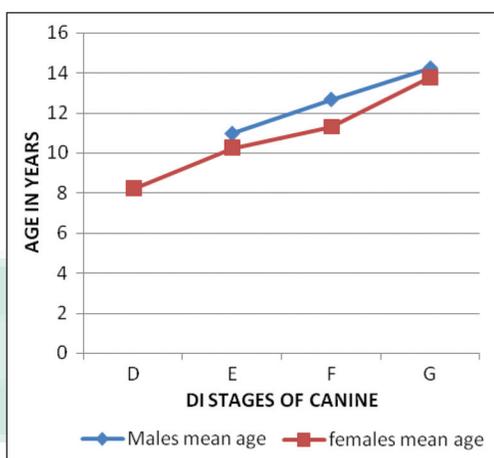

Figure 2: Mean age at each DI stage in both genders

the DI Stage F showed the highest percentage distribution (73%) at stage 2 of CVMI (pre-peak of pubertal growth spurt) and DI stage G showed a large percentage distribution in stage 3 of CVMI (peak of pubertal growth spurt). The DI stage H was associated with stages 4, 5, and 6 of CVMI (end of pubertal growth spurt).

Table 7 shows the association and distribution between the DI stages of mandibular canines and CVMI stages in females. The $\chi^2(15)$ was highly significant at 117.48 (*p* < 0.001). The Pearson contingency coefficient was 0.719 showing a highly significant association between DI and CVMI. The statistical values for female subjects were higher than for males, showing a stronger association in females.

Thus the null hypothesis was rejected and a significant relationship was found to exist between the CVMI stages and mandibular canine DI stages in both the genders. In females, the DI stage E corresponded to CVMI stages 1 and 2; DI stage G with CVMI stage 3, and DI stage H with CVMI stages 4, 5,

and 6. However, there was a scattered distribution of canine DI stages in females in the CVMI 3 stage, while it was better in males. A comparison of Tables 6 and 7 also shows that the DI in male subjects was more advanced than in female subjects with respect to the CVMI stages.

Discussion

OPGs were chosen for dental maturity assessment, as they are routinely available in orthodontic clinics, and the

mandibular region is clearly visible. The Demirjian *et al.*^[12] method was chosen for dental maturation assessment in the present study, because it is based on shape criteria and proportion of root length, using the relative value to crown the height rather than the absolute length. Therefore, the foreshortened or elongated projections of developing teeth will not affect their reliability of assessment.^[1]

The skeletal age assessment has been assessed on the lateral cephalograms, using the CVMI method described by Hassel and Farman.^[3] It is quick and relatively easy to perform. It omits the hand-wrist x-ray, thus avoiding excessive radiation exposure. Studies have found that CVMI is a reliable method for skeletal maturity assessment, equivalent to the hand-wrist x-rays, and shows greater reproducibility between the observers.^[3,13,14]

According to Hassel and Farman,^[3] CVMI 2 stage indicates the onset of accelerating growth velocity, CVMI 3 shows a period of rapid growth velocity, while CVMI 4 denotes the period of decelerating growth. The mean age for

each CVMI skeletal maturity level presented in Table 4 indicated that females mature earlier than males by an average of 1.5 years. This finding is in corroboration with other studies.^[1,15-18] Rwandese children and adolescents seem to be a little more advanced in skeletal maturation, as compared to other population groups.^[19]

Dental and Skeletal Maturity

The females were more advanced than the males in both dental and skeletal maturation, which was in accordance with the previous reports.^[7-9,13] However, the maturation patterns of tooth development in relation to CVMI skeletal maturity, was more advanced in males as compared to females [Tables 6 and 7]. At the same skeletal maturity stage, males had a higher distribution of the later dental developmental stages. This result was similar to the findings of previous studies.^[1,8,20,21] It is therefore suggested that tooth mineralization relative to the stages of skeletal maturation should be considered individually for both genders.

In this study, girls were found to mature earlier than boys, which was in agreement with the previous studies.^[1,8,21,22] Dental maturation also occurred earlier in girls than in boys, by almost a year, and completed earlier in girls. This suggested that a sexual dimorphism existed in mandibular canine tooth formation. However, Chertkow and Fatti^[24] reported no significant sex differences, while other studies reported an advanced trend in boys compared to girls.^[1,8,20] Conversely, Basaran *et al.* stated that boys showed late dental development.^[13]

The Pearson correlation coefficients between skeletal maturity and canine calcification stages in our study were 0.719 in females and 0.599 in males ($p < 0.001$), which confirmed the previous findings.^[1,6-8,20] It suggested that a moderate association existed between the skeletal and dental maturation stages.

In our study, DI stage F was coinciding well with CVMI stage 2 in males, but there was a scattered distribution of canine calcification stages in females in the CVMI 2 stage. Divyashree *et al.*^[9] found Stage F to be coinciding well with the pre-peak of skeletal development in the Indian sample, while Coutinho *et al.* found that in children from USA, the canine stage G was more indicative of the pre-peak of the growth spurt.^[7] Chertkow^[6] and Fatti and Chertkow^[20] had previously reported mandibular canine stage G coinciding with the early appearance of the sesamoid (which was equivalent to CVMI 2)^[3] in boys as well as in girls, while Krailassikari^[1] and So^[25] found no uniformity in canine development in the same skeletal maturity stage.

In our study, in CVMI 3 stage, the majority of the males was at DI stage G, while there was a scattered distribution of canine stages in females. At CVMI stages 4 and 5, in both genders, most of the canines were in stage G and H, that is, toward root completion, while 100% canines were in stage H at the CVMI 6 stage. It showed that canine stages could be considered as indicative of growth status in the beginning stages (stages E and F) and has more reliable significance in males than females. This was in accordance with the findings of Divyashree *et al.*^[9] in Indian subjects and Lu^[10] in Chinese subjects for the males.

It signifies that the interpretation of the relationship between mandibular canine calcification stages with the later stages of skeletal maturity is not meaningful. Mandibular canine calcification stages can only be used reliably in their earlier stages for predicting skeletal maturation levels. We have observed that there is no uniform distribution of the sample in the different stages of DI, which can be due to the small sample size and a larger age range of the study subjects. Future studies are recommended with a larger sample size and reduced age range. Also, a uniform number of study subjects must be selected in different age categories.

Clinical Implications

Knowledge of active growth is important for clinical decisions, especially for dentofacial orthopedic, surgical, and prosthetic treatment planning. Studies have reported that there is a greater skeletal response with myofunctional appliances if treatment is given during the peak height velocity period than during the pre-peak period.^[1] Thus for more orthopedic effects, the treatment must be started during the CVMI 2-3 stages. Treatment given after these stages may result in more dental than skeletal effects.^[1]

The relationship between the mandibular canine calcification stages and the skeletal maturity indicators can allow the clinician to more easily identify stages of the pubertal growth period. We found that the canine stage F in males and canine stage E in females may represent the CVMI 2 stage and can serve as a simple tool for evaluating the onset of the accelerating growth period. It can be easily incorporated into clinical practice by using the intra-oral periapical (IOPA) view for initial growth assessment of an individual.

Conclusion

A significant relation exists between the mandibular canine calcification and skeletal development, which is stronger in females than males. Canine stage F in males and canine stage E in females may represent the CVMI 2 stage and

indicate the onset of a period of accelerating growth. The findings of this study indicate that the mandibular calcification stages may be clinically used as a maturity indicator of the pubertal growth period, but only during the onset and accelerating phases. However, further study is recommended in a larger sample to corroborate the findings and to evaluate the mandibular maturation of the other teeth in relation to skeletal maturity.
